Multicenter Study of Intense Pulsed Light Therapy for Patients With Refractory Meibomian Gland Dysfunction

Reiko Arita, MD, PhD,†† Takanori Mizoguchi, MD, ‡‡ Shima Fukuoka, MD, ‡§ and Naoyuki Morishige, MD, PhD†¶

Purpose: To evaluate the efficacy of intense pulsed light (IPL) therapy combined with meibomian gland expression (MGX) for refractory meibomian gland dysfunction (MGD) in a prospective study conducted at 3 sites in Japan.

Methods: Patients with refractory obstructive MGD were enrolled and underwent 4 to 8 IPL-MGX treatment sessions at 3-week intervals. Clinical assessment included the Standard Patient Evaluation of Eye Dryness questionnaire; noninvasive breakup time of the tear film and interferometric fringe pattern as determined by tear interferometry; lid margin abnormalities, fluorescein breakup time of the tear film, corneal and conjunctival fluorescein staining (CFS), and meibum grade as evaluated with a slit-lamp microscope; meibomian gland morphology (meiboscore); and tear production as measured by the Schirmer test without anesthesia.

Results: Sixty-two eyes of 31 patients (17 women, 14 men; mean age ± SD, 47.6 ± 16.8 years) were enrolled. The Standard Patient Evaluation of Eye Dryness score (P < 0.001), noninvasive breakup time (P < 0.001), and interferometric fringe pattern (P < 0.001) were significantly improved after therapy, with 74% of eyes showing a change in the interferometric fringe pattern from 1 characteristic of lipid deficiency to the normal condition. Meibum grade, lid margin abnormality scores, fluorescein breakup time, and CFS were also significantly improved (P < 0.001, P < 0.001, P < 0.001, and P = 0.002, respectively) after treatment, whereas the meiboscore and Schirmer test value remained unchanged.

Conclusions: IPL-MGX ameliorated symptoms and improved the condition of the tear film in patients with refractory MGD and is therefore a promising treatment option for this disorder.

Key Words: meibomian gland dysfunction, meibomian gland, intense pulsed light

Meibomian gland dysfunction (MGD) is a chronic abnormality of meibomian glands characterized by terminal duct obstruction or qualitative or quantitative changes in the glandular secretion of meibum. Individuals with MGD thus manifest an imbalance in components of the tear film because of a deficiency of the lipid layer. The goal of MGD therapy is to provide long-term and stable amelioration of the symptoms of this condition by improving the quality of meibum or increasing meibum flow, thereby normalizing the balance between the lipid layer and the aqueous and mucin layers of the tear film and enhancing tear film stability, as well as by reducing inflammation. Common therapies include application of a warm compress; practice of lid hygiene; dietary supplementation with omega-3 fatty acids; forced meibum expression; intraductal probing; automated thermal pulsation; and administration of topical steroids, topical and oral antibiotics including topical cyclosporine and azithromycin, preservative-free artificial tears, lipid-containing eye drops, and topical diquafosol. Despite the variety of treatment options available, however, many patients with MGD are refractory to treatment and thus do not experience complete or long-term relief of symptoms.

Intense pulsed light (IPL) therapy is widely adopted cosmetically and therapeutically for removal of hypertrichosis, benign cavernous hemangiomas or venous malformations, telangiectasia, port wine stains, and other pigmented lesions. A systematic review found that IPL is an effective and well-tolerated treatment option for a range of dermatologic conditions, having been shown to result in reduction in the extent of telangiectasia and the severity of facial erythema. The efficacy of IPL therapy for patients with dry eye due to MGD was discovered serendipitously during IPL treatment of facial rosacea. Subsequent studies found that IPL is effective for improvement of subjective symptoms and objective findings in patients with mild to moderate MGD or dry eye. Indeed, the combination of IPL and meibomian gland expression (MGX) was found to ameliorate dry eye symptoms and to improve meibomian gland function in
patients with refractory dry eye, a cohort that included not only individuals with MGD but also those with graft-versus-host disease or Sjögren syndrome. The efficacy of such combination treatment in patients with moderate to advanced MGD was also recently demonstrated in a single-center study.

The purpose of this study was to evaluate the efficacy of IPL combined with MGX for patients with refractory MGD, including those with the most severe stage of the condition, in 3 centers in Japan. Refractory MGD was defined as that which had failed to respond to at least 3 types of conventional therapy prescribed in Japan including topical or systemic anti-inflammatory therapy, topical or systemic antibiotic therapy, topical lubricant eyedrops or ointment, automated thermal pulsation treatment, and intraductal probing over the course of at least 1 year. Given that most patients with MGD have applied a warm compress or practiced lid hygiene at home regardless of disease severity, these home-care remedies were not included as failed therapies in this study.

PATIENTS AND METHODS

The study was approved by the Institutional Review Boards of Itoh Clinic, Mizoguchi Eye Clinic, and Ohshima Eye Hospital, and it adhered to the tenets of the Declaration of Helsinki. The study was performed at each of the 3 participating centers from March to September 2017. Informed consent to study participation was obtained from each patient.

Patients

Individuals with refractory MGD attending Itoh Clinic, Mizoguchi Eye Clinic, or Ohshima Eye Hospital were enrolled in the study. Inclusion criteria included the following: 1) an age of at least 20 years; 2) a diagnosis of obstructive MGD based on the Japanese diagnostic criteria for MGD, which encompass ocular symptoms, plugged gland orifices, vascularity and irregularity of lid margins, and reduced meibum expression (meibum grade of >1, where grade 0 = clear meibum easily expressed, grade 1 = cloudy meibum expressed with mild pressure, grade 2 = cloudy meibum expressed with more than moderate pressure, and grade 3 = meibum could not be expressed even with strong pressure); 3) failure of at least 3 types of conventional MGD therapy to improve symptoms or objective findings for at least 1 year before study treatment; and 4) a Fitzpatrick skin type of 1 to 4 based on sun sensitivity and appearance. Exclusion criteria included the presence of active skin lesions, skin cancer, or other specific skin pathology or of active ocular infection or ocular inflammatory disease.

Experimental Design

Each patient underwent a series of 4 to 8 treatment sessions at 3-week intervals depending on the meibum grade (4, 6, or 8 sessions for grades 1, 2, and 3, respectively). Each patient was subjected to clinical assessment, as described below both before treatment at each visit and 4 weeks after the final treatment. All patients were asked to continue their current ocular medications. No patient was allowed to initiate therapy with a new topical or systemic agent for dry eye or MGD during the treatment course.

Clinical Assessment

The noninvasive breakup time (NIBUT) and the interferometric fringe pattern of the tear film were determined with a DR-10a tear interferometer (Kowa, Nagoya, Japan), as described previously. Lid margin abnormalities (plugging of meibomian gland orifices and vascularity of lid margins), breakup time [fluorescein breakup time (FBUT)] of the tear film and the corneal and conjunctival fluorescein staining score (CFS, 0–9) based on fluorescein staining, and meibum grade (0–3) were evaluated using a slit-lamp microscope. Morphological changes in the meibomian glands were assessed on the basis of the meiboscore (0–6), as determined by noninvasive meibography. Tear fluid production was measured by the Schirmer test, as performed without anesthesia. Symptoms were assessed with the Standard Patient Evaluation of Eye Dryness (SPEED) validated questionnaire (0–28).

IPL-MGX Procedure

Before the first treatment, each patient underwent Fitzpatrick skin typing, and the IPL machine (M22; Lumenis, Yokneam, Israel) was adjusted to the appropriate setting (range, 11–14 J/cm²). At each treatment session, both eyes of the patient were closed and sealed with IPL-Aid disposable eye shields (Honeywell Safety Products, Smithfield, RI). After generous application of ultrasonic gel to the targeted skin area, each patient received ~13 pulses of light (with slightly overlapping applications) from the right preauricular area, across the cheeks and nose, to the left preauricular area, reaching up to the inferior boundary of the eye shields. This procedure was then repeated in a second pass. Immediately after IPL treatment, MGX was performed on both upper and lower eyelids of each eye with an Arita Meibomian Gland Compressor (Katena, Denville, NJ). Pain was minimized during MGX by application of 0.4% oxybuprocaine hydrochloride to each eye.

Statistical Analysis

Data are presented as mean ± SD as indicated. Parameters were compared between before and after treatment with the paired Student t test. After testing for homogeneity of variance, we applied the independent t test to compare numerical variables and Fisher exact test to compare categorical variables between patients whose eyes showed a change in the SPEED score from baseline (ΔSPEED) of <5 or ≥5. P < 0.05 was considered statistically significant.

RESULTS

The characteristics of the study patients are presented in Table 1. Sixty-two eyes of 31 patients with refractory obstructive MGD, including 17 women and 14 men, were

than did those with a ΔSPEED of <5 (P < 0.001). There were no significant differences in sex distribution or the frequencies of at least 3 meibomian gland dropouts in 1 eyelid, history of contact lens wear, coincidence of aqueous-deficient dry eye, or previous ocular surgery between the 2 groups of patients (P = 1.0, 0.45, 1.0, 0.066, and 1.0, respectively).

DISCUSSION

This is the first prospective and multicenter study to show improvement in the subjective symptoms and objective signs of refractory severe MGD after a series of IPL treatments combined with MGX. Tear film stability, lipid layer dynamics, and meibomian gland function all responded positively to treatment, resulting in improvement in the condition of the tear film in the study patients. This study enrolled patients with refractory severe MGD at 3 centers and did not exclude those with a history of contact lens wear, ocular surgery, or any type of MGD management.

We found that IPL-MGX therapy was effective for management of refractory MGD, being associated with improvement in both lipid layer dynamics (tear interferometric fringe pattern) and NIBUT as determined with the DR-1α tear interferometer. IPL was also shown previously to improve the lipid layer grade as determined with the Tearscope Plus interferometer (Keeler, Windsor, United Kingdom) in patients with MGD.10 This latter study enrolled patients with mild to moderate MGD but not those with refractory MGD, with 82% of the treated eyes showing improvement in the lipid layer grade.10 In this study, after a course of 4 to 8 IPL-MGX treatments, 74% of eyes with refractory MGD showed a change in the tear interferometric fringe pattern from 1 characteristic of lipid deficiency to the normal condition, indicating that the balance between the lipid and aqueous layers of the tear film had improved. The NIBUT is characteristically reduced in patients with MGD.32 The previous study of the lipid layer grade also demonstrated a significant improvement in the NIBUT from 5.28 to 14.11 seconds after treatment of the patients with MGD with IPL.10 In this study, the NIBUT was increased from 3.3 to 7.8 seconds, representing a meaningful clinical improvement, with our previous study having shown that the cutoff value of the NIBUT for dry eye disease as measured by DR-1α is <5 seconds.25

Improvement of meibum quality and expressibility is a key factor in treatment of MGD. We found that meibum quality and expressibility were significantly better after IPL-MGX treatment in this study. Similar results were obtained in previous studies.9,12-15,17,20 IPL application increases skin temperature.10 Whereas the phase-transition temperature of meibum is 28°C in controls, it is >32°C in patients with MGD.33 Although eyelid warming at home has been found to be transiently effective for treatment of MGD,2 the temperature of the eyelid skin was found to increase to 34°C during the application of a warming device but then to decrease rapidly over 10 minutes after device removal.34 Such eyelid warming at home is thus not sufficient to support long-term melting of meibum.34 However, IPL has been found to

FIGURE 2. Change in the FBUT between baseline and 4 weeks after the final IPL-MGX treatment session.

FIGURE 3. Changes in the NIBUT (A) and dynamics of the lipid layer of the tear film, as revealed by a tear interferometric fringe pattern (B) between baseline and 4 weeks after the final IPL-MGX treatment session.
in 1 eyelid, indicative of the disease severity. Such severe disease was too difficult to manage even with a combination of several conventional therapies. However, a series of IPL-MGX therapy sessions were able to improve subjective symptoms and objective findings including meibum quality and quantity, lid margin abnormalities, and stability and homeostasis of the tear film.

The potential mechanisms for ameliorating subjective symptoms and objective findings of MGD are considered, as mentioned above, to promote melting of meibum,9,16 to attenuate local release of inflammatory factors from the abnormal vessels,18,37,38 and to reduce bacterial load of the eyelid margin.39

There are several limitations to our study. First, the study design was single arm and was based on both eyes of a small number of patients. Further studies with a larger number of patients and a control group are necessary. Second, the duration of follow-up was limited to 4 weeks after the final treatment. Longer follow-up periods will be necessary to assess the long-term effectiveness and safety of IPL treatment. Third, all the patients at each site continued their current medications during the study. A more controlled experimental design will be preferable for future studies. Fourth, IPL treatment is not covered by national insurance in Japan. Although the enrolled patients did not pay for IPL treatment in this study, this situation might introduce inherent bias.

In conclusion, our results suggest that IPL-MGX therapy is effective for patients with refractory MGD whose severe disease is difficult to manage with other conventional therapies. IPL-MGX thus has the potential to help many patients with MGD and is a promising modality for refractory MGD in particular.
